## ODEs in CPM cells: Cell cycle and proliferation

Cells divide according to an oscillatory ODE model representing the early cell cycle in Xenopus.

### Introduction

This multiscale model example shows

1. how to define a coupled system of continuous ODEs in discrete CPM cells
2. how to specify and change time scales between these model formalisms

### Model description

This model specifies an oscillatory ODE model representing the cell cycle in Xenopus oocytes using three components (CDK1, Plk1, APK) (Ferrell et al., Cell, 2011) (see `CellTypes`→`CellType`→`System`). This ODE model is coupled to 2D shaped CPM cells that perform divide based on the concentration of these components (see `CellTypes`→`CellType`→`Proliferation`→`Condition`). As in the early Xenopus cell cleavage, this leads to exponential growth of the number of cells, without increase of total cell volume.

### Time scales

Time scales are defined in the following fashion:

- The so-called global time scheme is defined in `Time` and here runs from 0 to 1 arbitrary time units. All models and plugins specify their updating scheme in terms of this global time scheme (e.g. `Analysis`→`Gnuplotter`→`interval`).
- The CPM time scale for cell motility and behaviors is defined in `CPM`→`MCSDuration`. This specifies the time that a single Monte Carlo step in the CPM lasts, in terms of the 'global time'. Here, the `MCSDuration` is  $1.0 \cdot 10^{-4}$  which means the CPM is executed 10.000 times during this simulation.
- For setting time of ODEs, one has to distinguish the (1) how often the ODEs are evaluated from (2) controlling the time scale of the ODE dynamics:
  1. The time scale of the ODE dynamics can be changed using `System`→`time-scaling`. When larger or smaller than  $1.0$ , this speeds up or slows down the dynamics,

without influencing the accuracy of the approximation.

2. The accuracy of the numerical approximation (and is equal to the  $\Delta t$  of the numerical solver) is controlled using **System→time-step** (and is automatically rescaled according to the time scale).

## Things to try

- Change the CPM time scale, relative to the ODE dynamics: Change **CPM→MCSDuration** to  $1.0 \cdot 10^{-3}$  or decrease to  $1.0 \cdot 10^{-5}$ . This makes cells to have less resp. more motility/relaxation in between cell divisions.
- Change the time scale of the ODE dynamics, relative to the CPM by altering **System→time-scaling**.

## Dictyostelium

Aggregation of amoebas through chemotaxis towards waves of cAMP.

# Video

## Introduction

This model shows chemotactic aggregation of Dictyostelium. It was constructed by students attending the [ECMI modeling week 2012](#) in Dresden.

## Model description

This model shows an interesting coupling between CPM cells and reaction-diffusion PDE. Cell state depends on the perceived concentration of cAMP, and determines whether a cell produces cAMP and whether it performs chemotaxis. The PDE is governed by a Fitzhugh-Nagumo-like model of an excitable medium, which causes traveling waves upon excitation. Chemotaxis through those waves causes cell aggregation.

Background colors indicate the cAMP concentration. Cells are color-coded according to their phase: excitable/resting (yellow), excited/chemotactic (green), refractory/resting (red).

## MembraneProperties: Cell polarization and chemotaxis

*Note: MembraneProperties are not available in public version of Morpheus.*

Cell dynamically re-polarizes in response to switching external gradient

**Video**

## Introduction

This model of cell polarity shows the coupling of three model formalisms:

- A cellular Potts model
- A PDE model, solved on the membrane of the cell
- And an external gradient.

The cell membrane polarizes in response to the external gradient. Chemotactic cell motility depends on the polarity of the cell and the external gradient.

## Description

This example implements two models of cell polarity: Meinhardt's substrate-depletion model and Edelstein-Keshet's wave-pinning model. The user can switch polarity model by **Disabling/Enabling** the relevant **System**.

The model defines a one-dimensional reaction-diffusion system (`MembraneProperty`) representing membrane-bound molecules, and is mapped to a cellular Potts model defining a discrete shaped cell. An external gradient, specified in a PDE, provides a signal for the polarization of the cell. In turn, the polarity of the cell influences its chemotactic behavior.

After a switch in direction of the gradient, the cell re-polarizes in the new direction and starts to move up the gradient, iff the wave pinning model has been selected.
